(Dated: February 6, 2008)

We analyze the behavior of the thermal conductivity in quasi-two dimensional superconductors with line nodes. Motivated by measurements of the anisotropy between the interplane and intraplane thermal transport in CeIrIn$_5$ we show that a simple model of the open Fermi surface with vertical line nodes is insufficient to describe the data. We propose two possible extensions of the model taking into account a) additional modulation of the gap along the axial direction of the open Fermi surface; and b) dependence of the interplane tunneling on the direction of the in-plane momentum. We discuss the temperature dependence of the thermal conductivity anisotropy and its low T limit in these two models and compare the results with a model with a horizontal line of nodes ("hybrid gap"). We discuss possible relevance of each model for the symmetry of the order parameter in CeIrIn$_5$, and suggest further experiments aimed at clarifying the shape of the superconducting gap.

PACS numbers:

I. INTRODUCTION

Symmetry classification of possible gap structures established the framework for separating conventional superconductors from their unconventional counterparts[1,2,3]. Superconductors with the order parameters that transform according to the trivial irreducible representation of the point symmetry group of the crystal are usually labeled conventional. If the order parameter transforms according to a non-trivial representation of the same group, the superconductor is called unconventional.

In the latter class the symmetry of the order parameter is lower than the full group symmetry. This lowering of symmetry is usually believed to be related to strong repulsive Coulomb interactions and specific pairing mechanisms (for example, due to magnetic fluctuations). As a result, determining the gap structure is one of the crucial steps in testing our understanding of the origin of superconductivity in a given material. An important group of unconventional superconductors are those with order parameter that vanishes (has nodes) for some directions at the Fermi surface.

Thermal conductivity is an exceptionally powerful probe for testing the shape of the gap in nodal superconductors since only the unpaired electrons (with momenta close to the nodal directions) carry entropy. The presence or absence of the nodes, and sometimes their type (point or line), can be inferred from the dependence of the thermal conductivity on the magnetic field and temperature. An additional test for the existence of line nodes is the so-called universality of the low-temperature coefficient of the thermal conductivity, $a_0 = \lim_{T\to 0} \kappa/T$ [4,5,6]. The universal behavior refers to the relative insensitivity of a_0 to the concentration of the impurity atoms and to the details of the scattering on individual impurity centers[7]. Physically, since impurity scattering is pairbreaking, it generates near-nodal quasiparticles which can carry heat, and whose lifetime is, in turn, is limited by scattering on the same impurities. For linear nodes the two effects cancel nearly exactly. In the high-T$_c$ cuprates, for example, the quantitative agreement between theoretical estimates of a_0 and the measured thermal conductivity was established[8,9]. However, determining the location of the nodes in the momentum space from such measurements is much harder.

The most direct tests measure the variation in the heat transport with the orientation of the applied magnetic field with respect to the nodal directions[10,11,12,13,14,15,16]. Long before such experiments were attempted, it was proposed that the *anisotropy* of the thermal conductivity along two different directions as a function of temperature allows to infer information about the gap structure[17,18]. Essentially, the measurement determines the predominant direction of the Fermi velocity for the nodal quasiparticles. Combined with the knowledge of the Fermi surface, measurements of the evolution of the anisotropy in the superconducting state impose stringent constraints on the possible loci of the nodes.

This method was applied to UPt$_3$[19], and the results argued convincingly for a line of nodes at $k_z = 0$. The main reason this experiment did not uniquely determined the gap structure is that theoretically expected results depend on the detailed shape of the Fermi surface and the superconducting gap, i.e. on the basis functions for the particular representation[20]. This detail apart, it is believed that the measurement provides a good test for the horizontal vs. vertical linear nodes.

Very recently the anisotropy of the thermal conductivity along inequivalent crystalline directions was measured in heavy fermion CeIrIn$_5$ by Shakeripour et al.[21]. The ratio of the c-axis to the in-plane thermal conductivity, κ_c/κ_a, rapidly decreases in the superconducting state. Similarity of the anisotropy evolution to that for UPt$_3$, where equatorial line of nodes is believed to exist, led the authors of Ref. 21 to suggest that the superconducting gap in CeIrIn$_5$ also has a horizontal line of nodes. This is surprising since CeCoIn$_5$, a close relative of CeIrIn$_5$, has vertical lines of nodes[15,22], and the prevailing belief is that the two compounds are quite similar (although some evidence points to different origin of superconductivity in the two systems[23]).

Consequently, in this paper we re-visit the analysis of the temperature dependence and the anisotropy of the thermal conductivity in nodal superconductors. Since both de Haas - van Alphen measurements, and band structure calculations show that CeIrIn$_5$ has an open, quasi-two dimensional piece of the Fermi surface with significant f-electron contribution[24], our main focus here is on such anisotropic systems. We discuss the implications of the measurements for the symmetry of the order parameter, and compare the anisotropy of the thermal conductivity for several models relevant not only to CeIrIn$_5$, but also to other systems with a quasi-two dimensional Fermi surface.

The remainder of the paper is organized as follows. In next section we introduce the basic experimental facts and theoretical considerations, formulating the models. The subsequent sections are devoted to the analysis of the proposed models. We then critically compare our results with experiment, and propose further measurements to test the gap symmetry in CeIrIn$_5$.

II. EXPERIMENTAL BACKGROUND

CeIrIn$_5$ is a member of the so called 115 series, which also include CeCoIn$_5$ and CeRhIn$_5$. While in the Rh system the f-electrons of Ce remain localized and undergo antiferromagnetic ordering, both Ir and Co compounds are paramagnetic heavy fermion metals. In both systems de Haas-van Alphen measurements and the band structure calculations indicate that a major sheet of the Fermi surface is quasi-two dimensional, although the energy dispersion along the c-axis is substantial, as evidenced by a very moderate anisotropy (~ 2) between the out of plane and in-plane normal state transport coefficients. In contrast to CeCoIn$_5$, which is a highly unconventional metal, likely close to a quantum critical point at finite magnetic field[25,26], CeIrIn$_5$ near the superconducting phase is a good Fermi liquid, and therefore its excitations should be adequately described by the calculations in the Fermi-liquid framework.

Both CeIrIn$_5$ and CeCoIn$_5$ are ambient pressure superconductors, and Knight shift measurements indicate singlet pairing[27,28]. Specific heat and in-plane thermal conductivity measurements[29], as well as penetration depth[30] and spin-lattice relaxation rate[27,28], show the existence of line nodes. In CeCoIn$_5$ there is overwhelming evidence for the vertical line nodes from the anisotropy of the thermal conductivity and specific heat under rotated magnetic field[15,22], and from the tunneling into the Andreev bound states[31]. Given the strong similarities between the Fermi surfaces it is tempting to conclude that the gap structure is similar in the two materials. There is, however, evidence pointing towards differences in the origin (and hence possibly in the type) of the superconducting state of the Co and Ir compounds[23].

Authors of Ref.21 measured the temperature dependence of the thermal conductivity in CeIrIn$_5$ along two inequivalent crystalline directions, $\kappa_c(T)$ (out of plane) and $\kappa_a(T)$ (in plane), and made two significant observations: a) The ratio $R(T) = \kappa_c/\kappa_a$ is nearly temperature-independent above the superconducting transition temperature, T_c, but is rapidly reduced with T at $T < 0.5T_c$ (Note that inelastic scattering yields a peak in thermal conductivity just below $T_c \sim 0.4$ K, which may lead to the decrease of $R(T)$ appearing very pronounced); b) The low T limit of the in-plane κ_a/T appears universal, but the interplane κ_c/T does not show the universal limit. Our goal below is to examine the possible origin and implications of this result.

III. BASIC CONSIDERATIONS AND MODELS

Independently of the choice of theoretical model, the results a) and b) above imply, prima facie, that the effect of superconductivity on the quasiparticles with the Fermi velocity predominantly in the plane is different from that for the quasiparticles moving along the c-axis: the states that carry entropy along the c-axis have a larger "effective gap" than those carrying heat current in the plane. Several processes of different physical origin may lead to this behavior. In the following we do not consider inelastic scattering; this is appropriate at low temperatures, $T \ll T_c$. The range of temperatures in Ref. 21 where the inelastic scattering can be neglected is not immediately clear from the data, note, however, that, if the inelastic scattering is isotropic, our conclusions regarding the anisotropy of the thermal transport are not affected.

Since the Fermi surface of CeIrIn$_5$ has several sheets, it is, of course, possible that the multiband effects are responsible for the observed behavior. However, without a microscopic theory detailing the gaps on each of the sheets, reaching reliable conclusions about the agreement between theory and experiment seems impossible, while phenomenological multiband theory has too many fitting parameters to seriously constrain possible gap structures. We aim to construct a minimal model that captures the essential physics of the the experimental observations, and therefore restrict ourselves to considering one electronic band.

Since most band structure and dHvA analyses suggest an important role of the quasi-two dimensional (open along the c-axis) band, we choose such a band for our approach. We approximate it by a simple nearest neighbor tight binding expression

$$\epsilon(\boldsymbol{k}) = \frac{k_x^2 + k_y^2}{2m} - 2t(\boldsymbol{k}) \cos(k_z c), \qquad (1)$$

where k_i are the components of the quasiparticle momentum, $\boldsymbol{k}$, c is the lattice spacing in the z direction, m is the effective mass, and $t(\boldsymbol{k})$ is the interplane tunneling matrix element. In all but one of our models we take $t(\boldsymbol{k})$ to be momentum-independent. We show below however, that the model with $\boldsymbol{k}$-dependent interplane tunneling that provides a viable path towards explaining the experimental results, even with the assumption of vertical, rather than horizontal, nodes.

We consider singlet order parameters, and begin with the simple model of vertical line nodes similar to the order parameter in CeCoIn$_5$, introducing the azimuthal in-plane angle $\phi = \arctan k_y/k_x$,

- **Model A:** $t(\boldsymbol{k}) = t$, and
  $\Delta(\boldsymbol{k}) = \Delta_0 \cos 2\phi$.

We show in the next section that this model is incompatible with the experimental observations. Physically, the Fermi surface is cylindrically symmetric and the gap depends only on the azimuthal angle, ϕ, while the z-axis component of the Fermi velocity is ϕ-independent. As we show below in Sec. V, these conditions ensure that the ratio $\kappa_c/\kappa_a \equiv \kappa_{zz}/\kappa_{xx}$, is temperature-independent even in the superconducting state.

This constraint needs to be relaxed to explain the experimental results, and we consider several possible models. First, we show that for a tight-binding Fermi surface it can be expected, from microscopic considerations, that the gap also acquires a weak modulation along the c-direction, while retaining vertical lines of nodes, and therefore consider

- **Model B:** $t(\boldsymbol{k}) = t$, and
  $\Delta(\boldsymbol{k}) = \Delta_0(1 + \delta \cos k_z c) \cos 2\phi$.

While in this model there exists a temperature-dependent anisotropy, we find that this dependence is generally weak, and hence unlikely to provide a satisfactory explanation of the experimental observations (although we cannot exclude it).

In the second approach to lifting the constraints of model A we consider a situation with vertical line nodes, but where the nodal quasiparticles are less efficient than the normal electrons (on average) in transporting heat along the c-axis compared to the xy plane. To model this we note that the measured and calculated Fermi surface of CeIrIn$_5$ is not rotationally symmetric[24], and that the energy dispersion of the electrons along the z-axis clearly depends on the direction of the in-plane momentum. This dependence is expected in the D_{4h} symmetry, and $t(\boldsymbol{k})$ is determined by the structure of the overlapping wave functions for the quasi-two dimensional band. We therefore introduce the angle dependence into the interplane tunneling, preserving the crystal symmetry in the plane, and propose

- **Model C:** $t(\boldsymbol{k}) = t_0 + t_1 \cos^2 2\phi$, and
  $\Delta(\boldsymbol{k}) = \Delta_0 \cos 2\phi$.

For $t_1 > 0$ the interplane tunneling is smaller for the nodal quasiparticles than for antinodal ones, which ensures the T-dependence of the anisotropy ratio. The situation is somewhat reminiscent of that in the high-T$_c$ cuprates where, in the absence of orthorhombic distortion, the interplane tunneling of the nodal quasiparticles is suppressed, i.e. $t_0 = 0$ [32], and therefore the observed temperature dependence of the Josephson plasma resonance frequency[33] and the c-axis penetration depth[34,35] is different from that suggested by the simple density of states power counting. We show that such a model gives a significant temperature-dependent anisotropy of the thermal conductivity.

Finally, we consider a model with horizontal, rather than vertical line nodes, similar to the hybrid E_{1g} gap proposed for UPt$_3$, with broken time-reversal symmetry. The basis function of the representation is described as $k_z(k_x + ik_y)$. For open Fermi surface we require periodicity along the z-direction, and the appropriate basis function is $(k_x + ik_y) \sin k_z c$. The excitation spectrum and the thermal conductivity are only sensitive to the gap amplitude, $|\Delta(\boldsymbol{k})| = k_\perp |\sin k_z c|$, where $k_\perp = (k_x^2 + k_y^2)^{1/2}$. Since our consideration of Model B shows (see the analysis below) that weak modulation does not change the anisotropy qualitatively, we ignore it, and consider

- **Model D:** $t(\boldsymbol{k}) = t$, and
  $|\Delta(\boldsymbol{k})| = \Delta_0 |\sin k_z c|$.

We show that, this model also gives a substantially temperature-dependent ratio κ_{zz}/κ_{xx}. Moreover, we point out that from the data of Ref. 21 it is impossible to distinguish Model C from Model D, and suggest further measurements to probe the gap structure in CeIrIn$_5$.

We are now ready to consider each model in detail. In order to make connection with experiment, we largely focus on the thermal conductivity and its anisotropy

$$R(T) = \frac{\kappa_{zz}(T)}{\kappa_{xx}(T)}. \tag{2}$$

We begin by briefly looking at the normal state properties.

IV. NORMAL STATE

The Fermi surfaces for the models A through D are shown in Fig. 1. In each case we transform to the cylindrical coordinates and parameterize the Fermi surface by the azimuthal angle $\phi = \arctan k_y/k_x$, and the c-axis quasimomentum k_z. The Jacobian of the transformation from variables k_x, k_y, k_z to variables ϵ, k_z, ϕ is unity, and therefore no angle-dependence of the normal state density of states appears. We denote the Fermi energy E_F, and define the Fermi momentum at $k_z = \pm\pi/2c$ as $k_F = \sqrt{2mE_F}$.

In models A, B, D above the tunneling t is ϕ-independent. In that case, the radius of the Fermi surface is $k_0(k_z) = k_F\sqrt{1 + (2t/E_F)\cos(k_z c)}$, and the compo-

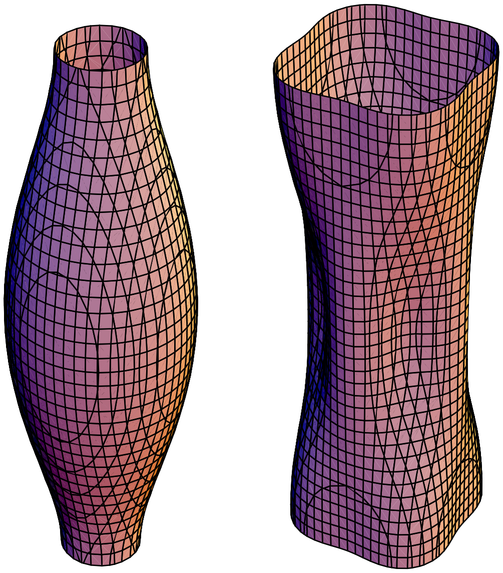

FIG. 1: Fermi surfaces for models considered in the paper. Left panel: Models A,B, and D. Right panel: Model C. Notice the similarity between the Fermi surface shown in that panel and the Fermi surface suggested for CeIrIn$_5$ in Ref. 24.

nents of the Fermi velocity are

$$\begin{aligned} v_x &= \frac{k_0\cos\phi}{m} = v_F\sqrt{1+(2t/E_F)\cos(k_zc)}\cos\phi, &\text{(3a)}\\ v_y &= \frac{k_0\cos\phi}{m} = v_F\sqrt{1+(2t/E_F)\cos(k_zc)}\sin\phi, &\text{(3b)}\\ v_z &= 2tc\sin(k_zc) = \frac{t}{E_F}(k_Fc)v_F\sin(k_zc), &\text{(3c)} \end{aligned}$$

where $v_F = k_F/m$. In the normal state the anisotropy of the transport coefficients is given simply by

$$R_n \equiv \frac{\sigma_{zz}}{\sigma_{xx}} = \frac{\kappa_{zz}/T}{\kappa_{xx}/T} = \frac{\langle v_z^2\rangle}{\langle v_x^2\rangle}, \tag{4}$$

where the average over the Fermi surface is

$$\langle A\rangle = \int_0^{2\pi}\frac{d\phi}{2\pi}\int_{-\pi}^{\pi}\frac{d\chi_z}{2\pi}A(\phi,k_z), \text{ and } \chi_z = k_zc. \tag{5}$$

For the simple model above $R_n = (t/E_F)^2(k_Fc)^2$.

We can obtain a very rough estimate of the parameter values relevant for CeIrIn$_5$ from the dHvA measurements and the band structure calculations[24]. For the quasi-cylindrical piece of the Fermi surface the typical radius is 1/5 of the Brillouin Zone size, $k_F \approx 2\pi/(5a)$, where a is the in-plane lattice constant. In this material $c/a \sim 1.6$, so that $k_Fc \approx 2$. The normal state resistivity ratio, $R_n \sim 0.4$, implying $t/E_F \sim 0.3$.

For model C the situation is slightly more complex. We still have

$$v_z = 2t(\phi)c\sin(k_zc) = 2t(\phi)c\sin\chi_z, \tag{6}$$

and therefore

$$\langle v_z^2\rangle = \frac{v_F^2}{2}(k_Fc)^2\left[\frac{t_0^2}{E_F^2}+\frac{t_0t_1}{E_F^2}+\frac{3}{8}\frac{t_1^2}{E_F^2}\right]. \tag{7}$$

At arbitrary in-plane k the x-component of the velocity is

$$v_x = \frac{k\cos\phi}{m} + \frac{2t_1}{k}\sin\phi\sin4\phi\cos\chi_z, \tag{8}$$

and, consequently, at the Fermi surface,

$$\langle v_x^2\rangle = \frac{v_F^2}{2} + v_F^2\frac{t_1^2}{E_F^2}\left\langle\frac{\sin^2\phi\sin^2 4\phi\cos^2\chi_z}{1+2t(\phi)/E_F\cos\chi_z}\right\rangle. \tag{9}$$

Since we work in the regime $t_{0,1}/E_F \ll 1$, we can ignore the corrections from the term $t(\phi)/E_F$ in the denominator as they appear only at the order $(t/E_F)^4$, and write

$$\langle v_x^2\rangle = \frac{v_F^2}{2}\left[1+\frac{3}{16}\frac{t_1^2}{E_F^2}\right]. \tag{10}$$

For the conductivity anisotropy of 2.5 cited above, the *maximal* value of t_1/E_F, when there is no t_0 component, is approximately $(t_1/E_F)^2 \approx 4/15$, which corresponds to the contribution of the second term of less than 5% to the in-plane transport in the normal state. Its effect in the superconducting state is even smaller, since the t_1-dependent part of v_x vanishes along the nodal directions. Consequently, we ignore the t_1-dependent contribution to the in-plane transport hereafter.

V. MODEL A: CONSTANT HOPPING, VERTICAL LINE NODES

The thermal conductivity of a superconductor with the gap function whose average over the Fermi surface vanishes is given by[20,36]

$$\frac{\kappa_{ii}}{T} = \frac{N_0}{4}\int_0^\infty\frac{d\omega}{T}\left(\frac{\omega}{T}\right)^2\operatorname{sech}^2\left(\frac{\omega}{2T}\right)K_i(\omega,T), \tag{11}$$

$$K_i(\omega,T) = \frac{1}{\widetilde{\omega}_1\widetilde{\omega}_2}\,\mathrm{Re}\left\langle v_i^2\,\frac{\widetilde{\omega}^2+|\widetilde{\omega}|^2-2|\Delta_{\mathbf{k}}|^2}{\sqrt{\widetilde{\omega}^2-|\Delta_{\mathbf{k}}|^2}}\right\rangle.$$

Here N_0 is the normal state density of states, and the renormalized frequency $\widetilde{\omega} = \widetilde{\omega}_1 + i\widetilde{\omega}_2 = \omega - \Sigma(\widetilde{\omega})$, where Σ is the self-energy due to impurity scattering. For the model with $\Delta_{\mathbf{k}} = \Delta_0\cos2\phi$, and the hopping that is ϕ-independent, we immediately find for different orientations of the heat current

$$\begin{aligned}\left\langle v_i^2\,\frac{\widetilde{\omega}^2+|\widetilde{\omega}|^2-2|\Delta_{\mathbf{k}}|^2}{\sqrt{\widetilde{\omega}^2-|\Delta_{\mathbf{k}}|^2}}\right\rangle &= \frac{2\eta_i}{\pi} &\text{(12)}\\ &\times\left[\widetilde{\omega}\,\mathrm{E}\left(\frac{\Delta_0}{\widetilde{\omega}}\right)+\frac{|\widetilde{\omega}|^2-\widetilde{\omega}^2}{2\widetilde{\omega}}\,\mathrm{K}\left(\frac{\Delta_0}{\widetilde{\omega}}\right)\right],\end{aligned}$$

where E and K are the complete elliptic integrals, and

$$\eta_x = v_F^2, \qquad \eta_z = (2tc)^2. \tag{13}$$

Therefore the anisotropy of the thermal conductivity in the superconducting state remains unchanged compared to the normal state, $R_s = R_n = (t/E_F)^2(k_F c)^2$. Moreover, in this model the universal (nearly independent on impurity concentration) low temperature limit, obtained from Eq.(12), is[4,5,6,20]

$$a_{0,i} = \lim_{T\to 0} \frac{\kappa_i}{T} = \frac{\pi}{6} \frac{N_0 \eta_i}{\sqrt{\gamma^2 + \Delta_0^2}} E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right), \quad (14)$$

for both in-plane and out of plane directions. In Eq.(14) γ is the low-energy scattering rate, $\widetilde{\omega}(\omega = 0) = i\gamma$, and E is the complete elliptic integral. For clean superconductors, $\gamma \ll \Delta_0$, and we have

$$\frac{1}{\sqrt{\gamma^2+\Delta_0^2}} E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right) \approx \frac{1}{\Delta_0} + O\left(\frac{\gamma^2}{\Delta_0^2}\right), \quad (15)$$

so that $a_{0,i} = \eta_i \pi N_0/(6\Delta_0)$, universal and independent of the impurity scattering rate.

This constant and temperature independent ratio $R_s(T)$ is in contradiction to the experimental measurements of Ref. 21, and therefore model A does not provide a satisfactory description of the superconducting state of CeIrIn$_5$.

VI. MODEL B: MODULATED GAP

A. Microscopic justification

The symmetry classification does not uniquely determine the functional form of the superconducting gap around the Fermi surface. The gap can be given by any combination of the basis functions transforming according to the chosen irreducible representation. For example, in a cubic system, both a constant gap and that varying as $k_x^4 + k_y^4 + k_z^4$ have the same symmetry properties.

Of course, any $\boldsymbol{k}$-space variation of the gap beyond that imposed by symmetry requirements costs condensation energy, and therefore, all other things being equal, the simplest basis functions often provide the most stable superconducting state. A conventional superconductor with a spherical Fermi surface strongly prefers a fully isotropic gap, while a strongly anisotropic quasi two-dimensional system with a circular Fermi surface and the dominant pairing in the B_{1g} channel is likely to have the gap with the $k_x^2 - k_y^2$ momentum dependence. This is the reason for using the familiar notation of s-wave for the former case, and $d_{x^2-y^2}$ for the latter.

On the other hand, superconductivity is an instability of the Fermi surface towards pairing, and therefore it is natural to expect that in real materials with complex Fermi surfaces the gap structure is also more complex. The correct gap can only be determined from the microscopic theory of superconductivity. To solve Eliashberg equations in superconductors with electron-phonon mediated pairing, Allen introduced the Fermi surface harmonics[37], which have the symmetry of the Fermi surface, are orthonormal, and are convenient basis functions for the expansion of the superconducting pairing field.

In the absence of microscopic theory we use similar symmetry arguments, and go beyond lowest order basis functions. For simplicity, we continue to consider the $d_{x^2-y^2}$ gap symmetry, $\Delta(\hat{\boldsymbol{k}}) \propto \cos 2\phi$; all our considerations apply equally well to other gaps with vertical line nodes, such as d_{xy}. Choice of this symmetry determines the irreducible representation of the crystal point group. In a system with the Fermi surface open along the c-axis, we need to add to this point group the invariance with respect to translations by a reciprocal lattice vector along z. In the even (odd) channel the basis functions for translation are $\cos nk_z c$ ($\sin nk_z c$), with n integer. Therefore quite generally the singlet $d_{x^2-y^2}$ gap has the form

$$\Delta(\hat{\boldsymbol{k}}) = \sum_n \Delta_n \cos(nk_z c)\cos 2\phi. \quad (16)$$

Similar interaction for s-wave pairing was considered by Bulaevskii and Zyskin[38], and for d-wave symmetry by Rajagopal and Jha[39,40]. Note that since even powers of k_z, and therefore $\cos(nk_z c)$, transform according to a trivial representation of the tetragonal point group, the functions with different n belong to the same representation and can be mixed.

The degree of mixing is, of course, determined by the pairing interaction. We consider a separable model,

$$V(\hat{\boldsymbol{k}}, \hat{\boldsymbol{k}}') = \Phi(\hat{\boldsymbol{k}})\Phi(\hat{\boldsymbol{k}}'), \quad (17)$$

where

$$\Phi(\hat{\boldsymbol{k}}) = \sum_n V_n \cos(nk_z c)\cos 2\phi. \quad (18)$$

To illustrate the behavior of the model, and to be consistent with keeping only the nearest neighbor layer hopping in the energy dispersion, Eq.(1), we truncate the expansion at $n = 1$, so that

$$V(\hat{\boldsymbol{k}}, \hat{\boldsymbol{k}}') = V_0\left[1 + \lambda_1(\cos\chi_z + \cos\chi_z') + \lambda_2 \cos\chi_z \cos\chi_z'\right]\cos 2\phi \cos 2\phi'. \quad (19)$$

To the same accuracy the gap is given by

$$\Delta(\boldsymbol{k}) = \Delta_0\left[1+\delta\cos\chi_z\right]\cos 2\phi, \tag{20}$$

and is determined from the self-consistency equation (for pure superconductor in the weak-coupling limit)

$$\Delta(\boldsymbol{k}) = \pi T\sum_{|\omega_n|<\Omega_0}\int_{-\pi}^{\pi}\frac{d\chi_z}{2\pi}\int_0^{2\pi}\frac{d\phi}{2\pi}\frac{\widetilde{V}(\hat{\boldsymbol{k}},\hat{\boldsymbol{k}}')\Delta(\hat{\boldsymbol{k}}')}{\sqrt{\omega_n^2+\Delta^2(\hat{\boldsymbol{k}}')}}. \tag{21}$$

Here $\widetilde{V}(\hat{\boldsymbol{k}},\hat{\boldsymbol{k}}') = N_0 V(\hat{\boldsymbol{k}},\hat{\boldsymbol{k}}')$, $\omega_n = \pi T(2n+1)$ are the fermionic Matsubara frequencies, and Ω_0 is the cutoff energy for the pairing interaction.

Formally, the gap given by Eq.(20) allows for a horizontal line of nodes when $\delta > 1$. This is, however, physically unlikely. In the interaction $V(\hat{\boldsymbol{k}},\hat{\boldsymbol{k}}')$ above, λ_2 is the relative strength of the pairing in neighboring planes compared to the in-plane pairing, so that $|\lambda_2| < 1$. Generally we also expect $\lambda_1 \sim t/E_F < 1$ [38], so that the gap modulation along the c-axis is insufficient to produce horizontal lines of nodes. Inversely, if the interaction strengths in different channels in Eq.(19) are comparable, we cannot truncate the expansion at the lowest order terms. Therefore, while in principle the symmetry considerations allow the gap in Eq.(20) to have both horizontal and vertical nodes, the model considered here can only be used if it yields small to moderate values of δ.

Consider first the linearized equations for the transition temperature, T_c. Introducing dimensionless coupling constant $g = N_0V_0$, we find that T_c and δ satisfy

$$\begin{aligned} 1 &= \frac{g}{2}\left[1+\frac{\lambda_1\delta}{2}\right]\ln\frac{2\gamma_E\Omega_0}{\pi T_c}, && \text{(22a)}\\ \delta &= \frac{g}{2}\left[\lambda_1+\frac{\lambda_2\delta}{2}\right]\ln\frac{2\gamma_E\Omega_0}{\pi T_c}. && \text{(22b)}\end{aligned}$$

Here $\gamma_E \approx 0.58$ is the Euler's constant. Note that in the absence of the λ_1 term in the pairing interaction the equations for the temperatures of the transition into the states $\Delta_0\cos 2\phi$ and $\Delta_1\cos\chi_z\cos 2\phi$ decouple, and each is reduced to the standard BCS expression, $T_c^{(n)} = (2\gamma_E/\pi)\Omega_0\exp(-2/g_{eff}^{(n)})$, with the effective coupling constants in the $\cos n\chi_z$ channels g and $\lambda_2 g/2$ for $n = 0$ and $n = 1$ respectively. For $\lambda_2/2 < 1$ this implies that $T_c^{(0)} > T_c^{(1)}$, so that the simple $\cos 2\phi$ gives the dominant order parameter.

For the generic case $\lambda_1 \neq 0$, however, the two channels are coupled, and the transition occurs directly into the c-axis modulated state $\Delta = \Delta_0(1+\delta\cos\chi_z)\cos 2\phi$. The transition temperature is

$$T_c = \frac{2\gamma_E}{\pi}\Omega_0\exp(-2x_0/g), \tag{23}$$

where

$$\begin{aligned} x_0 &= \frac{2}{1+\lambda_2/2+D^{1/2}}, && \text{(24)}\\ D &= (1-\lambda_2/2)^2+2\lambda_1^2. && \text{(25)}\end{aligned}$$

We assumed that the coupling λ_2 is not too repulsive. The transition temperature depends on the magnitude, but not on the sign of λ_1. On the other hand, the modulation, $\delta = 2(x_0^{-1}-1)/\lambda_1$, depends on the sign of λ_1, and can be either positive or negative.

The modulation amplitude, δ, is generally T-dependent. Consider the self-consistency equation at $T < T_c$,

$$1 = g\pi T\sum_{|\omega_n|<\Omega_0}\int_{-\pi}^{\pi}\frac{d\chi_z'}{2\pi}\int_0^{2\pi}\frac{d\phi'}{2\pi}\left[1+\lambda_1\cos\chi_z'\right]\frac{\left[1+\delta\cos\chi_z'\right]\cos^2 2\phi'}{\sqrt{\omega_n^2+\Delta_0^2(1+\delta\cos\chi_z')^2\cos^2 2\phi'}} \tag{26a}$$

$$\delta = g\pi T\sum_{|\omega_n|<\Omega_0}\int_{-\pi}^{\pi}\frac{d\chi_z'}{2\pi}\int_0^{2\pi}\frac{d\phi'}{2\pi}\left[\lambda_1+\lambda_2\cos\chi_z'\right]\frac{\left[1+\delta\cos\chi_z'\right]\cos^2 2\phi'}{\sqrt{\omega_n^2+\Delta_0^2(1+\delta\cos\chi_z')^2\cos^2 2\phi'}} \tag{26b}$$

In the linearized form considered above, all the terms in the integrand linear in $\cos\chi_z'$, vanish by symmetry. On the other hand, below T_c, when Δ^2 term in the denominator is important, these terms give a finite contribution to the gap equation. Moreover, in contrast to the conventional "one-channel" systems, the cutoff frequency Ω_0 cannot be removed from the self-consistency equations completely. As a consequence, δ acquires temperature dependence.

Of course, in the weak coupling limit this dependence is insignificant: in both integrals in Eq.(26) the greatest contribution is from the range $\Delta_0 \ll \omega_n \leq \Omega_0$, and therefore essentially insensitive to the absence or presence of the gap. In most situations the dependence on the cutoff vanishes already for $\Omega_0/T_c \geq 10$. This is seen from the self-consistently determined temperature evolution of the gaps in the two channels computed using Eqs.(26) and shown in the left panel of Fig.2. The corresponding plot

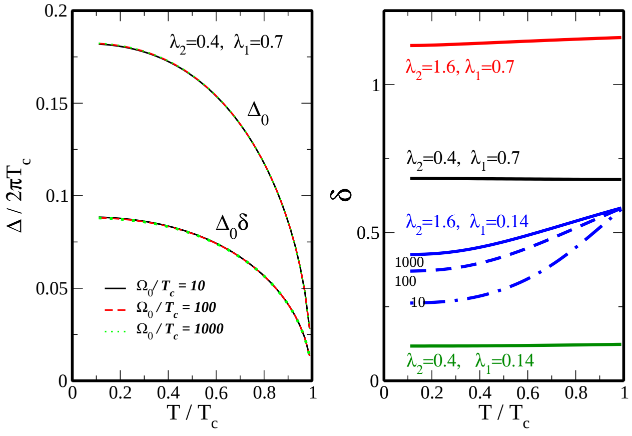

FIG. 2: Temperatures dependence of the gap parameters in Model B. Left panel: temperature evolution of the gaps in two channels for typical coupling values. Note the independence of the result on the cutoff frequency Ω_0: for different cutoffs $\Omega_0/T_c = 10, 100, 1000$ the curves lie on top of one another. Right panel: Temperature dependence of the gap anisotropy, δ for different coupling constants. Note the temperature variation of the anisotropy in the regime of moderately large $\lambda_2 = 1.6$ and small $\lambda_1 = 0.14$, where we present the results for $\Omega_0/T_c = 10, 100, 1000$.

of the modulation, δ, in the right panel of Fig.2 demonstrates that the modulation is temperature-independent for most parameter values.

We find that one exception is the somewhat artificial situation when a) the bare transition temperatures into the two states are very close, $\lambda_2 \approx 2$ so that $T_c^{(0)} \approx T_c^{(1)}$, *and* b) $\lambda_1 \ll 1$. While δ is still temperature-independent for $\Omega_0/T_c \to \infty$, the temperature variations persist to large values of the cutoff, see Fig.2. Part of the reason is that the value of $\delta(\lambda_1 \to 0, \lambda_2 \to 2)$ at T_c obtained above depends on the order in which the limits are taken: setting $\lambda_2 = 2$ first gives $\delta = \sqrt{2}$, while taking the limit $\lambda_1 \to 0$ first for a finite value of $1 - \lambda_2/2$ yields $\delta = 0$.

Physically, at the point $\lambda_2 = 2, \lambda_1 = 0$ the linearized equations, Eq.(22), decouple, and give no information on the values of Δ_0 and $\Delta_1 = \Delta_0\delta$. As is well known, the gap amplitudes are determined by the fourth order terms in the Ginzburg-Landau expansion of the free energy, or, equivalently, by the third order terms in the gap equations. We find that inclusion of such terms gives three different possible solutions for Δ_0 and Δ_1. Two of them are trivial, $\Delta_0 \neq 0, \Delta_1 = 0$ (lowest energy, as expected), and $\Delta_0 = 0, \Delta_1 \neq 0$. However, we find that there is a third solution with $\Delta_1/\Delta_0 = \delta = const$, which has the highest energy of the three. At the same time for $\lambda_2 = 2$ and any *finite* λ_1 $\delta = const$ corresponds to the lowest free energy, which suggests a singular limit $\lambda_1 \to 0$. This is confirmed by carrying our the expansion of δ in $1 - T/T_c$, at finite λ_1, where we find that the coefficients are singular for $\lambda_2 = 2$. This suggests a strong dependence of the energies of the three stationary points on parameters, and on temperature.

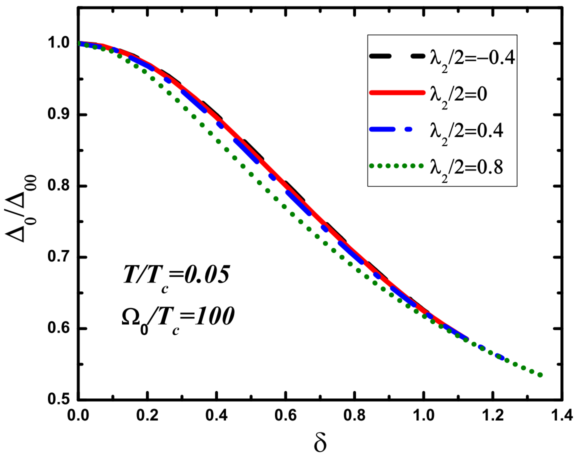

FIG. 3: Gap amplitude as a function of the gap anisotropy for Model B at low temperature. The BCS value $\Delta_{00} = 2.14 k_B T_c$. Note the smooth evolution of the gap amplitude across the value $\delta = 1$, where a horizontal line of nodes appears.

Away from the non-physical point $\lambda_2 = 2, \lambda_1 = 0$, the numerical solution of the self-consistency equations, Eqs.(26) shown in Fig.2 makes it clear that we can use the gap $\Delta = \Delta_0[1 + \delta\cos\chi_z]\cos 2\phi$ with temperature independent δ. However, at low temperatures Δ_0/T_c is no longer at the BCS ratio of 2.14, but depends on the value of δ. This dependence is computed numerically, shown in Fig.3, and is used in subsequent computation of the thermal conductivity.

B. Thermal conductivity

We use Eq.(11) with $\Delta = \Delta_0[1 + \delta\cos\chi_z]\cos 2\phi$ to evaluate the temperature dependence of the thermal conductivity in a quasi-two dimensional superconductor. For our calculations we used the impurity scattering in the unitarity limit, with the normal state $\Gamma_N = 0.007 T_c$. While both κ_{zz} and κ_{xx} show the standard dependence on the scattering rate for unconventional superconductors[6], the anisotropy ratio is essentially insensitive to impurity concentration in the clean limit $\Gamma_N \ll T_c$. The results are shown in Figs. 4 and 5. One point of note is that the c-axis thermal conductivity is even in δ, while the in-plane transport is sensitive to whether the largest or the smallest gap occurs for $k_z = 0$, where the in-plane Fermi velocity is the greatest, see Eq.(3).

Of immediate interest to us is the temperature dependence of the anisotropy, $R(T)/R_n$, which is shown in Fig. 6. The qualitative understanding of the temperature dependence relies on the observation that the modulation changes the gap most significantly in the regions $\chi_z = 0, \pm\pi$, where the quasiparticle velocity is strictly in the ab plane, with no component along the c-axis. Consequently, for $\delta > 0$ the in-plane conductivity is reduced compared to that of a superconductor with an unmodulated gap, while for $\delta < 0$ it is increased. As a result, for $\delta > 0$ the anisotropy ratio κ_{zz}/κ_{xx} below T_c is enhanced compared to the normal state value, while for $\delta < 0$ it is reduced. Notice that for our model κ_{zz} is insensitive to the sign of δ since points at the Fermi surface where $\cos\chi_z = \pm a$ ($\chi_z = \alpha, \pi - \alpha$) have identical values of the Fermi velocity, and therefore contribute equally to the c-axis thermal conductivity.

The residual anisotropy in the $T \to 0$ limit can be computed analytically once we recognize that, prior to integration over the z-component of the momentum, for each value of χ_z the contribution of the kernel to the conductivity is universal in complete analogy to a two-dimensional d-wave superconductor with the gap $\Delta(\chi_z)$. Consequently, the ratio of the residual low temperature terms is ($\lambda = 2t/E_F$)

$$\begin{aligned}\frac{R_0}{R_n} &= 2\left[\int_{-\pi}^{\pi}\frac{\sin^2(\chi_z)d\chi_z}{1+\delta\cos\chi_z}\right]\Big/\left[\int_{-\pi}^{\pi}\frac{(1+\lambda\cos(\chi_z))d\chi_z}{1+\delta\cos\chi_z}\right]\\ &= 2\frac{1-\sqrt{1-\delta^2}}{\delta^2}\left[\frac{\lambda}{\delta}+\left(1-\frac{\lambda}{\delta}\right)\frac{1}{\sqrt{1-\delta^2}}\right]^{-1}. \qquad (27)\end{aligned}$$

This result is shown in Fig. 6. The experimentally determined $R_s(T)/R_0$ is as low as 0.5 at temperatures of the order of $0.2\mathrm{T}_c$[21]. This can only be achieved for large negative values of the gap anisotropy, $|\delta| = -\delta \gtrsim 0.8$, when the gap nearly vanishes in the equatorial plane of the Fermi surface. This value is possible for sufficiently strong coupling λ_1, but we consider it not very likely in CeIrIn$_5$. In this model both κ_{zz} and κ_{xx} are universal, albeit with different values, and therefore future doping studies of this material will be able to test the universality of the z-axis thermal conductivity.

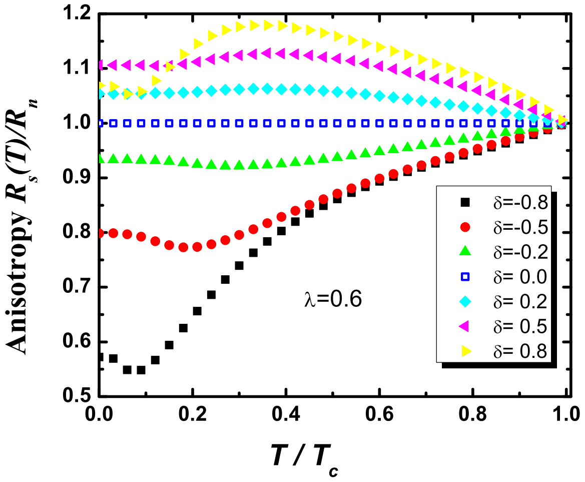

FIG. 6: Anisotropy of the thermal conductivity for the model.

VII. MODEL C: MODULATED INTERPLANE HOPPING

A. Justification and general considerations

In quasi-two dimensional systems the interplane matrix element depends on the overlap of the atomic orbitals contributing to the bands close to the Fermi surface. Therefore, in general, the in-plane and out-of-plane motion of the quasiparticles are coupled, and, in writing the tight-binding ansatz for the open Fermi surface along the c-axis, it is necessary to recognize that the matrix element t is a function of the in-plane direction of the momentum, ϕ. Moreover, simply looking at the quasi-2D sheet of the Fermi surface of CeIrIn$_5$ as obtained by band-structure calculations and by dHvA measurements[24], it is clear that The Fermi surface is not rotationally invariant, and therefore it is necessary to account for the angle-dependence of tunneling. For the Fermi surface of a general shape $k_F^2 = k_x^2 + k_y^2 - 2t\cos\chi_z$ the difference between the maximal and minimal values of the radius, $k_0^2(k_z)$ is $4t$. In the 115 series this difference is greater along the [110] direction than along the [100] direction, which suggest that t is ϕ-dependent[24].

In the normal state this dependence does little beyond replacing t with the appropriate average over the directions, see Sec. IV. In a superconducting state with an anisotropic gap, however, the effect of the modulation of the interplane hopping can be much more pronounced. The best studied example is the high-T$_c$ cuprates, where, on the basis of band structure calculations, $t(\phi)$ is expected to vanish along the directions of the nodes in the gap[32]. Among the manifestations of this effect are the high power law in the temperature variation of the c-axis penetration depth (T^5 rather than T in the pure limit)[34], and weak dependence of the Josephson plasma resonance frequency on temperature at $T \ll T_c$ [33].

In the analysis of the thermal conductivity it is easy to see that any directional dependence $t(\phi)$ results in a deviation of the anisotropy ratio, $R_s(T)$, from its normal state value, R_n, even for a superconducting gap that has pure d-wave form, $\Delta = \Delta_0 \cos 2\phi$, with no k_z-dependence. This is simply because the quasiparticle velocity, v_z, now acquires a dependence on the angle ϕ, which affects the evaluation of the thermal conductivity kernel, K_z, see Eq.(11). Moreover, since the universal low temperature behavior is due to near-nodal quasiparticles, any suppression of the hopping matrix element in the vicinity of the nodes reduces the contribution of these quasiparticles to the c-axis transport, making it non-universal, while preserving the universality of the low temperature limit for the in-plane conductivity. Therefore assuming a modulated hopping may provide a route towards the explanation of the experimental results.

B. Model and thermal conductivity

Once again we adopt the model energy dispersion of the form

$$\epsilon(\boldsymbol{k}) = \frac{k_x^2 + k_y^2}{2m} - 2t(\phi)\cos(k_z c), \tag{28}$$

where

$$t(\phi) = t_0 + t_1 \cos^2 2\phi, \tag{29}$$

which is the simplest anisotropic form satisfying the tetragonal symmetry. This additional ϕ dependence does not affect the in-plane thermal conductivity, κ_{xx}, but does modify the out of plane κ_{zz}. As discussed in Sec.IV, to a good approximation the normal state anisotropy ratio is

$$R_n = \frac{\kappa_{zz}}{\kappa_{xx}} = \left[\frac{t_0^2}{E_F^2} + \frac{t_0 t_1}{E_F^2} + \frac{3}{8}\frac{t_1^2}{E_F^2} \right] (k_F c)^2. \tag{30}$$

For simplicity, and in agreement with the results of the previous section showing that small c-axis modulation of the gap does not yield significant corrections to the anisotropy ratio in the superconducting state, we consider a d-wave gap in this calculation. In agreement with the discussion above, we are interested in the situation when the interplane transport is suppressed along the nodal directions, and therefore take $\Delta = \Delta_0 \cos 2\phi$.

Neglecting the small corrections to the in-plane Fermi velocity due to the angle-dependence of t, as discussed in Sec.IV, we find

$$K_x = \frac{v_F^2}{\pi \widetilde{\omega}_1 \widetilde{\omega}_2} \mathrm{Re}\left[\widetilde{\omega}\, \mathrm{E}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) + \frac{|\widetilde{\omega}|^2 - \widetilde{\omega}^2}{2\widetilde{\omega}} \mathrm{K}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) \right]. \tag{31}$$

The kernel for the interplane conductivity is more complex,

$$K_z = \frac{4c^2}{\pi \widetilde{\omega}_1 \widetilde{\omega}_2} \mathrm{Re}\Bigg\{ t_0^2 \left[\widetilde{\omega}\, \mathrm{E}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) + \frac{|\widetilde{\omega}|^2 - \widetilde{\omega}^2}{2\widetilde{\omega}} \mathrm{K}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) \right] + 2 t_0 t_1 \left[\widetilde{\omega}\, I_{1e}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) + \frac{|\widetilde{\omega}|^2 - \widetilde{\omega}^2}{2\widetilde{\omega}} I_{1k}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) \right] \tag{32}$$

$$+ t_1^2 \left[\widetilde{\omega}\, I_{2e}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) + \frac{|\widetilde{\omega}|^2 - \widetilde{\omega}^2}{2\widetilde{\omega}} I_{2k}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) \right] \Bigg\}, \tag{33}$$

where

$$
\begin{aligned}
I_{1e}(x) &= \frac{2x^2-1}{3x^2}E(x) - \frac{x^2-1}{3x^2}K(x), && (34)\\
I_{1k}(x) &= \frac{K(x)-E(x)}{x^2}, && (35)\\
I_{2e}(x) &= \frac{8x^4-3x^2-2}{15x^4}E(x) + \frac{2(1+x^2-2x^4)}{15x^4}K(x), && (36)\\
I_{2k}(x) &= -\frac{2}{3}\frac{1+x^2}{x^4}E(x) + \frac{2+x^2}{3x^4}K(x). && (37)
\end{aligned}
$$

The $T=0$ limit, which is important for the comparison with the universal limit, can also be readily evaluated as a function of the low energy scattering rate, γ, by setting $\widetilde{\omega} = i\gamma$. We reproduce the standard result for the in-plane conductivity,

$$
\lim_{T\to 0}\frac{\kappa_{xx}}{T} = \frac{\pi}{6}\frac{N_0 v_F^2}{\sqrt{\gamma^2+\Delta_0^2}}E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right), \tag{38}
$$

while for the interplane thermal conductivity we find

$$
\begin{aligned}
\lim_{T\to 0}\frac{\kappa_{zz}}{T} = \frac{2\pi}{3}\frac{N_0 c^2}{\sqrt{\gamma^2+\Delta_0^2}}\Bigg\{ & t_0^2 E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right) + 2t_0 t_1 \frac{\gamma^2}{\Delta_0^2}\left[K\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right) - E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right)\right] && (39)\\
& + t_1^2\frac{\gamma^2}{\Delta_0^2}\left[E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right) - 2\frac{\gamma^2}{\Delta_0^2}\left[K\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right) - E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right)\right]\right]\Bigg\}. && (40)
\end{aligned}
$$

In the clean limit, $\gamma \ll \Delta_0$, the residual in-plane conductivity is universal,

$$
\lim_{T\to 0}\frac{\kappa_{xx}}{T} \approx \frac{\pi}{6}\frac{N_0 v_F^2}{\Delta_0}, \tag{41}
$$

while the c-axis conductivity, for $t_0/t_1 > \gamma/\Delta_0$, is given by

$$
\lim_{T\to 0}\frac{\kappa_{zz}}{T} \approx \frac{2\pi}{3}\frac{N_0 c^2}{\Delta_0}t_0^2, \tag{42}
$$

which implies that the residual anisotropy ratio is

$$
\frac{R_0}{R_n} = \left[1 + \frac{t_1}{t_0} + \frac{3t_1^2}{8t_0^2}\right]^{-1} < 1. \tag{43}
$$

Even for a very moderate anisotropy ratio, $t_1/t_0 = 2$ (which, for samples with $\gamma/\Delta_0 \sim 0.1$ is well within the range of the approximation), the anisotropy ratio at low temperature is already low at about 22%.

The reduction of the anisotropy is even more pronounced for the cases of extreme anisotropy, $t_0/t_1 \ll \gamma/\Delta$, when

$$
\frac{R_0}{R_n} \approx \frac{8}{3}\frac{\gamma^2}{\Delta_0^2}\left[1 + \frac{t_0}{t_1}\ln\frac{4\Delta_0}{e\gamma}\right] \ll 1. \tag{44}
$$

Consequently in this model the residual anisotropy ratio can be arbitrarily small depending on the purity. If there are no symmetry requirements for the hopping matrix element to vanish for the nodal directions, in most situations we do not expect t_0 and t_1 to differ by an order of magnitude; this suggests that the residual linear term is visible in the c-axis thermal conductivity, but may be significantly smaller than its in-plane counterpart. While the results above give a rough estimate of the effect of impurities on the residual anisotropy, it is worth noting that

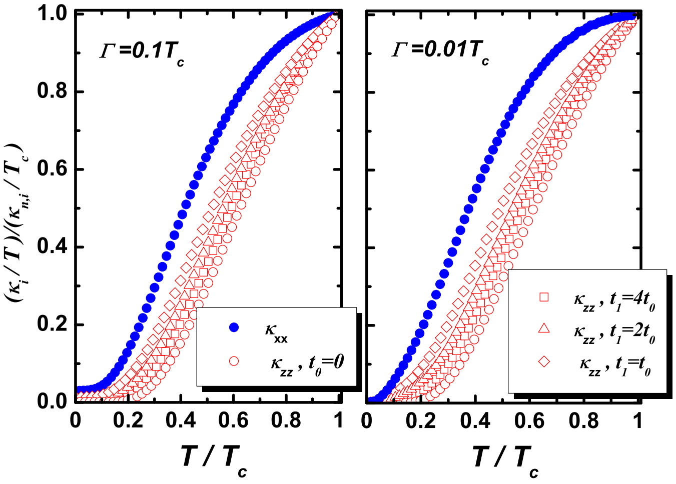

FIG. 7: Temperature dependence of the in-plane and the interplane thermal conductivity for the model with modulated hopping. The impurities are assumed to be in the unitarity limit, with Γ the normal state scattering rate.

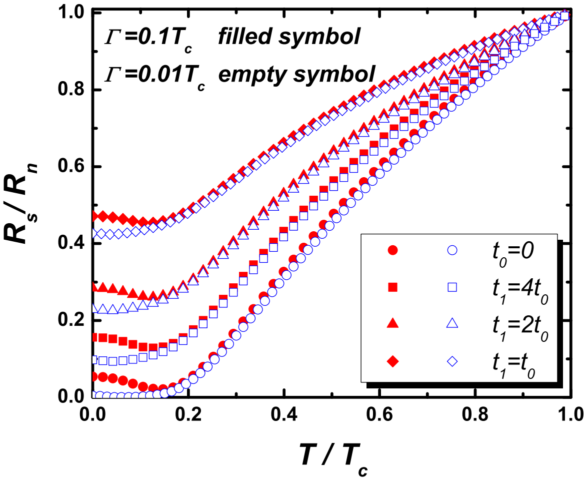

FIG. 8: Temperature dependence of the anisotropy of the interplane to the intraplane thermal conductivity. Note that the residual value is increasing with increasing t_0/t_1.

disorder is likely to make the interplane hopping more isotropic, and therefore tends to restore the anisotropy to the the normal state value faster that what Eq.(44) indicates.

VIII. MODEL D: HYBRID GAP

So far we looked at the models with vertical line nodes, motivated by possible similarities between CeIrIn$_5$ and CeCoIn$_5$, and attempted to reconcile them with the experimental measurements. Of course, in the absence of any information about the nodal structure, a natural explanation for the observed anisotropy is that, in analogy to UPt$_3$, the system has a horizontal line of nodes, and therefore the nodal quasiparticles do not contribute to the c-axis transport. We consider this model now.

The hybrid gap belongs to the representation that transforms as $\widehat{k}_z(\widehat{k}_x \pm i\widehat{k}_y)$. The basis function for this representation over an open Fermi surface is $(k_x \pm ik_y)\sin\chi_z$, and therefore, for, if we take the weakly modulated limit, $k_{F,x}^2 + k_{F,y}^2 \approx$const, the gap amplitude is $|\Delta(\chi_z, \phi)| = \Delta_0|\sin\chi_z|$. If we take into account the fourfold, rather than cylindrical, shape of the Fermi surface, there may be additional small modulation of this gap with the component of the Fermi momentum in the xy plane as a function of z: based on our results for Model B in Sec.VI, we ignore these. Then the density of states, and the in-plane thermal conductivity for this model are identical to that for a system with vertical line nodes, while the interplane thermal conductivity kernel is given by

$$K_z = \frac{4t^2c^2}{\pi\widetilde{\omega}_1\widetilde{\omega}_2}\,\mathrm{Re}\left[\widetilde{\omega}\, I_{1e}\left(\frac{\Delta_0}{\widetilde{\omega}}\right) + \frac{|\widetilde{\omega}|^2 - \widetilde{\omega}^2}{2\widetilde{\omega}}\, I_{1k}\left(\frac{\Delta_0}{\widetilde{\omega}}\right)\right] \tag{45}$$

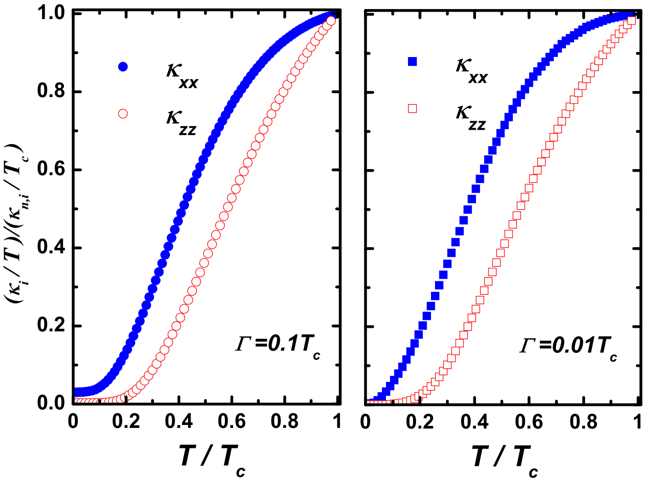

FIG. 9: Temperature dependence of the in-plane and the interplane thermal conductivity for the hybrid gap. The impurities are assumed to be in the unitarity limit, with Γ the normal state scattering rate.

The temperature dependence of κ_{xx} and κ_{zz} is shown in Fig. VIII, and the corresponding anisotropy ratio for the hybrid gap is given in Fig. VIII for the hybrid gap for different values of the impurity scattering. At low T the in-plane thermal conductivity is universal, while the interplane conductivity,

$$\begin{aligned}\lim_{T\to 0}\frac{\kappa_{zz}}{T} &\approx \frac{2\pi}{3}\frac{N_0t^2c^2}{\sqrt{\gamma^2+\Delta_0^2}} \qquad (46)\\ &\quad\times\frac{\gamma^2}{\Delta_0^2}\left[K\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right) - E\left(\frac{\Delta_0}{\sqrt{\gamma^2+\Delta_0^2}}\right)\right]\\ &\approx \frac{2\pi}{3}\frac{N_0t^2c^2}{\Delta_0}\frac{\gamma^2}{\Delta_0^2}\ln\frac{4\Delta_0}{e\gamma}, \qquad (47)\end{aligned}$$

gives the residual anisotropy

$$\frac{R_0}{R_n} \approx \frac{\gamma^2}{\Delta_0^2}\ln\frac{4\Delta_0}{e\gamma}. \tag{48}$$

This result is clearly non-universal. Notice that the dependence on the impurity scattering here differs from the γ/Δ_0 result obtained for UPt$_3$ in Ref. 20. The reason for the discrepancy is that for the hybrid gap and a Fermi surface closed along the c-axis the quasiparticles contributing the most to the c-axis conductivity are near the north and south pole. For the open Fermi surface these quasiparticles are absent, and the c-axis conductivity is reduced by an additional factor of γ/Δ_0. It is also obvious, from comparing this with the results of the previous section, that the residual anisotropy can be close for the models C and D, and may not provide the unequivocal distinction between the two.

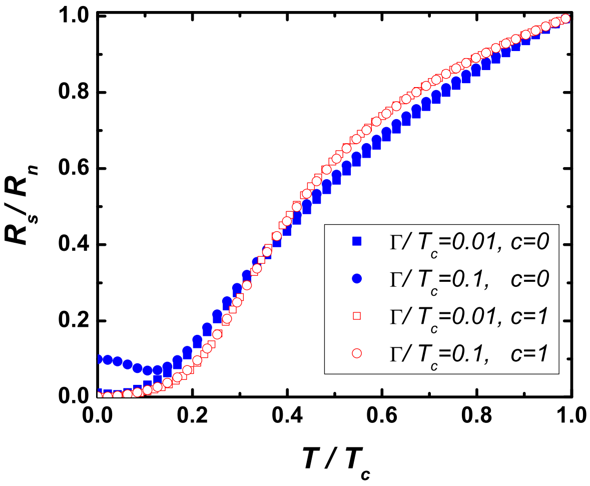

FIG. 10: Temperature dependence of the anisotropy of the interplane to the intraplane thermal conductivity for the hybrid gap. For comparison, we include results with deviations from the unitarity scattering limit.

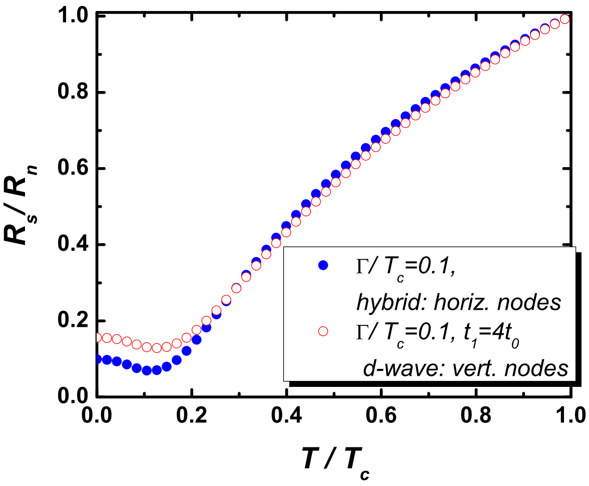

FIG. 11: Comparison of the temperature dependence for the hybrid and the d-wave gap.

IX. DISCUSSION.

It follows from experiment that the low-T value of the anisotropy of the thermal conductivity is below 25% of the normal value. The analysis above shows that model A (simple d-wave with constant interplane coupling) does not give results that can explain the observed anisotropy. Model B (weakly modulated, along the c-axis, amplitude of the d-wave gap) shows some tendency towards the temperature-dependent anisotropy, but, in our view, requires fine tuning if it were to explain the measurements of Ref. 21. On the other hand, both model C (modulated interlayer hopping, vertical line nodes) and model D (horizontal line nodes) give very similar behavior of the thermal conductivity as a function of temperature, with a low residual value of the anisotropy κ_c/κ_a, and therefore may be relevant to CeIrIn$_5$. Distinguishing between the two based purely on the thermal conductivity data may not be easy, as is seen from the comparison in Fig.11, which shows that, for sufficiently high anisotropy of t_1/t_0, there is essentially no difference in the behavior of the ratio κ_c/κ_a as a function of temperature between the two models.

There are notable differences between the results presented for either model and the experimental observations of Ref. 21. In experiment, the anisotropy ratio does not decrease below 0.5 for temperatures as low as $0.1T_c$, and there is no sign of saturation of the ratio below $0.15T_c$ as in theoretical analysis. This is due to strong inelastic scattering that results in a peak in κ_c/κ_a at about $0.3T_c$, but which is not included in our analysis here. Correspondingly, the low-T fit to experiment is done just below the peak, and the rapid decrease of the anisotropy may be related to the inelastic scattering.

The low residual value of the thermal conductivity anisotropy implies, in model C, highly anisotropic tunneling, $t_1 \geq 2t_0$. Published band structure data do not allow to reliably extract this ratio from fitting the quasi-two dimensional sheet of the Fermi surface, but this is the task that perhaps should be attempted in near future. In the meantime, we propose several experiments that have the potential to provide additional information to resolve the question of vertical vs. horizontal line nodes.

1. *Direct measurement of the specific heat and/or thermal conductivity in the vortex state under a rotated applied field.* This is, in our view, the best test for the existence of the line nodes. If, for the field rotated in the xy plane, no difference in the specific heat is found across the H-T phase diagram for the field direction along [110] vs. [100] direction, it is likely that there no vertical lines of nodes. If, on the other hand, such anisotropy is found and develops in agreement with theoretical predictions[41,42], this would be a strong evidence for d-wave, rather than hybrid, gap.

   At the same time, it is possible, although, in our view, unlikely, that there is gap modulation *both* in the plane and along the c-axis. Therefore measurements of the specific heat and thermal conductivity when the field is rotated in the zy or xz plane should be used to eliminate this possibility, and directly probe for horizontal line nodes. Low superconducting transition temperature of CeIrIn$_5$ and inelastic scattering require that these measurements be done at temperatures below ∼150mK.

2. *Measurement of the c-axis thermal conductivity in CeCoIn$_5$.* In the Co compound there is a general agreement that there are vertical line nodes. Measurements of the temperature evolution of the anisotropy κ_c/κ_a in that compound, and comparison with CeIrIn$_5$, while short of proof, would provide a test for the connection between the

anisotropy and the location of the nodes. Note that there is some evidence for remaining unpaired electrons in the superconducting state of $\mathrm{CeCoIn_5}$ (at least upon La-doping)[43], which leads to a residual metallic linear term for both directions of the heat current. However, as it was suggested that the fraction of these quasiparticles can be determined experimentally[43], their contribution can be subtracted, and the remaining anisotropy used to test the differences and similarities between $\mathrm{CeCoIn_5}$ and $\mathrm{CeIrIn_5}$.

3. *c-axis penetration depth measurements.* In analogy to cuprates, if the interplane transport is suppressed along the nodal directions, the c-axis penetration depth should either be not linear in T at $T \ll T_c$ (for $t_1 \gg t_0$) or have a small range of linear T behavior, with the coefficient much smaller than that inferred from the density of states varying as E/Δ_0. In $\mathrm{CeCoIn_5}$ the c-axis penetration depth is linear in T, and observation of the non-linear behavior in $\mathrm{CeIrIn_5}$ would point towards differences between the two systems. Unfortunately, we expect that, for reasons similar to those outlines for the thermal conductivity, it would be difficult to distinguish model C from model D on the basis of this measurement. Negative result, however (linear, in T, $\lambda_c(T)$) would be difficult to reconcile with the thermal conductivity measurements.

4. *Doping studies of residual c-axis thermal conductivity in $\mathit{CeIrIn_5}$.* In Fig.12 we show the evolution of the residual thermal conductivity along the c-axis, in units of the expected universal value for that direction, as a function of the low-energy scattering rate, γ. Notice that the increase in κ_{zz}/T for the hybrid gap is slow, while for the modulated interplane hopping of model C it is faster. In reality we expect that addition of impurities will tend to make the interplane hopping more isotropic in addition to introducing pairbreaking, and therefore the increase in the residual value of κ_{zz}/T will be even faster than that suggested by Fig.12. We therefore predict that, if model C of vertical line nodes with modulated t is realized, disordering the sample will produce a much more pronounced effect on the interplane thermal conductivity than that suggested by a hybrid gap.

X. CONCLUSIONS

In conclusion, we investigated the constraints placed on the shape of the superconducting gap in $\mathrm{CeIrIn_5}$ by the results of Shakeripour et al[21], assuming a one-band model with the Fermi surface open along the c-axis of the crystal. We find that the temperature evolution of the anisotropy between the transport along the c-axis and in the plane is incompatible with a simple d-wave gap over a quasi-two dimensional Fermi surface, such as often assumed in the studies of related compound, $\mathrm{CeCoIn_5}$. The temperature variation of the anisotropy shows that the c-axis conductivity is affected more significantly than its intraplane counterpart by the opening of the superconducting gap. This implies that the ability of the unpaired quasiparticles to carry heat current along the c-axis is impaired relative to their contribution to the in-plane transport. This disparity can arise either from the gap anisotropy or the Fermi surface properties. We explored several models where such modulation has different physical origin.

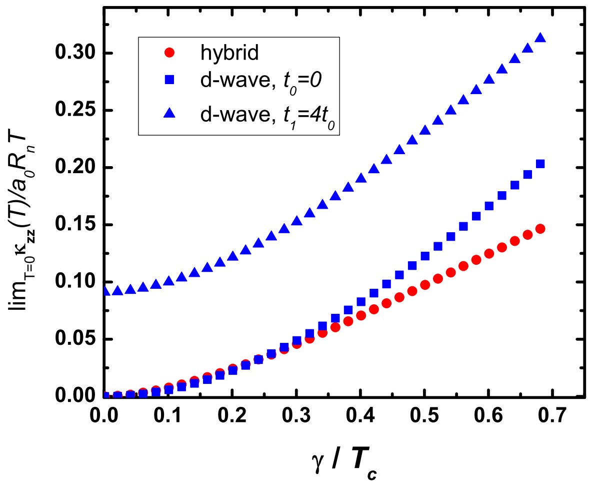

FIG. 12: Increase of the residual thermal conductivity with impurity scattering rate.

We find that a weakly c-axis modulated d-wave gap does not easily provide satisfactory agreement with experiment, although may do so with fine tuning of the parameters. Of the models with constant interplane hopping, that with **horizontal line nodes** most naturally account for the anisotropy, in partial agreement with the argument of Shakeripour et al.

Remarkably, we also find that an alternative model, where the c-axis hopping depends on the direction of the in-plane quasiparticle momentum, yield results that agree with the experimental data even if purely d-wave gap, with **vertical line nodes**, is assumed. Such an agreement requires substantial variation of the hopping between the nodal and the antinodal directions, in qualitative agreement with the analysis of the Fermi surface obtained in the dHvA measurements.

Given that there is some evidence for a distinct superconducting dome in $\mathrm{CeIrIn_5}$ it is clearly very important to determine the shape of the gap. We therefore suggested several possible experiments aimed directly at distinguishing the two situations and hope that further analysis will help resolve the uncertainty regarding the gap symmetry in this material. We also believe that the analysis above is generally relevant to a number of unconventional superconductors with a quasi-two-dimensional parts of the Fermi surface.

XI. ACKNOWLEDGEMENTS

We are very indebted to H. Shakeripour and L. Taillefer for discussing their results with us before publication, and to M. A. Tanatar for correspondence. We are also grateful to C. Capan for critical reading of the manuscript. This research was supported in part by the Board of Regents of Louisiana.
